Abstract

Benchmarking has been suggested as a useful regulatory tool for water companies in both developed and developing countries, specially due to the predominance of public firms in these sectors. However, in order to be effective, the comparisons should reflect differences in the firms' performances, rather than capture differences in their operating contexts. In this paper I apply a conditional data envelopment analysis (DEA) benchmarking technique that specifically controls for this, i.e., the conditional DEA approach. As a result, I find that conditioning on the population density in each firm's area of operation affects the estimated efficiencies in a significant way. The results are consistent with previous findings in other countries (which use different methodologies), and are new in the case of Peru.

Keywords: Public enterprise, water, efficiency, DEA

Introduction

Providing incentives for the efficient performance of water companies in developing countries is a complex issue, not least because of the prevalence of state-owned companies in these sectors. While the theoretical

incentive regulation literature has largely focused on profit-maximizing firms, empirical studies have simultaneously shown evidence that would contradict this behavioral paradigm in the case of government-owned firms.¹

The empirical evidence in the water sector, however, points to a slow productivity growth in most instances, irrespectively of the ownership configuration. For example, Saal, Parker & Weyman-Jones (2007) found increased technical change in the UK in the years following the privatization, but, also, equally significant efficiency losses in the newly-privatized water and sewerage companies, summing up to a non-existent net effect.² In the case of Peru, where the companies have not been privatized, Lin & Berg (2008) did find some productivity growth in the period 1998-2002 (mostly from technical change, no efficiency gains), but very modest.³

Therefore, the question of how to provide incentives for efficiency to public companies remains open. One common approach taken by the regulatory agencies, as in Peru, has been the use of publicly benchmarking the companies in the sector, with the hope that the public pressure from stakeholders provide the incentives for efficient performance. In fact, in the case of Netherlands, De Witte & Saal (2010) found positive effects on prices and efficiency from this simple approach, named as “sunshine regulation” by the authors.

The objective of this study is to contribute to this literature by proposing a method, within the DEA framework, to benchmark the productive efficiency of the firms in the Peruvian water sector, but taking into account the heterogeneity in the operating context that the companies face. As suggested by Berg & Lin (2008), “to be of use to regulators (...), and to be accepted by other stakeholders, performance comparisons must be robust to promote confidence that the performance rankings do indeed reflect managerial skill rather than accidents of geography or history” (p.794). Although DEA as a benchmarking technique has been proposed and implemented in previous studies (Berg & Lin, 2008; Lin, 2005), these studies did not take into account the heterogeneity in the firms’ operating contexts.

In the context of input-oriented efficiency analysis, this means that input usage requirements can be different in different operating contexts. For example, in cities with low population density, the amount of inputs (i.e., length of water network) required to reach a certain output level can be higher than in more highly densely populated areas. In this sense, the ideal would be to perform the comparison conditional on having relatively similar levels of population density. This is precisely the objective of the conditional DEA method, proposed in Daraio & Simar (2005). In order to keep the practical applicability at a simple level, this method is applied within a deterministic DEA approach.⁴

The previous literature in the Peruvian case suggest the importance of the contextual (also called “environmental”) heterogeneity, beyond the control of the firms, to partially explain differences in performance. Corton (2003), for example, shows that the number of districts in the area of operation and the natural region where the firm is located are statistically significant to explain the variation in operating costs (controlling for length of mains).

¹For example, Dewenter & Malatesta (2001), studying a very heterogeneous sample of firms in several sectors, find that government-owned firms are significantly less profitable than private firms, and tend to be more labor intensive. On the other hand, Seim & Waldfoegel (2013), in a study about of liquor retail stores, conclude that the behaviour of the public monopoly is best rationalized as “profit maximization with profit sharing”.

²Portela, Thanassoulis, Horncastle & Maugg (2011) extended the analysis for the period 1993-2007, and even finds a *decline* in productivity starting in 2005.

³Also, Estache, Perelman & Trujillo (2005) concluded that there is scant evidence of any differential overall performance between public and private operators in the water sector, after surveying productivity studies in developing countries.

⁴Berg & Lin (2008) show that deterministic DEA can be considered a robust benchmarking technique in the Peruvian case, by showing that the performance rankings produced with this technique are not too dissimilar to those produced with stochastic DEA techniques, theoretically more robust to outlier observations.

The concern in controlling for the heterogeneity of the operating context is shared with studies about other countries. For example, Tupper & Resende (2004) proposed a regression-based method to clean the effect of contextual variables on the estimated efficiencies (they take away the variation explained by the contextual variables, using a Tobit regression model), and applied it to the water sector in Brazil. The main difference between their methods and the ones applied here is that the conditional DEA methodology does not impose parametric constraints on the relation between the contextual variable and the unconditional DEA estimated efficiencies.

In regards to the empirical evidence in developed countries, De Witte & Saal (2010) applied the method proposed in this study for the Dutch case, but under an stochastic DEA framework. They also found important to condition the DEA estimates on the population density. Similarly, Vidoli (2011) applied a novel nonparametric method to evaluate the dependency of the efficiency estimates on contextual variables in the Italian case, and finds a predominant role to the population density.

The remaining of the paper is organized as follow: Section 2 briefly describes the main institutional features of the water industry in Peru, Section 3 describes the benchmarking methodologies applied, Section 5 describes the details of the model specification, as well as the main features of the data at hand, Section 5 presents the main results, and Section 6 concludes.

The Water Sector in Peru

The water and sewage sectors in Peru are a decentralized system, formed by the municipality-owned companies that are under the supervision of SUNASS (Superintendencia Nacional de Servicios de Saneamiento), the agency in charge of regulating the operation of the firms in the sector.

Starting in 1999, SUNASS established a benchmark system to evaluate the performance of the companies under its supervision. This system was based, originally, on nine indicators, grouped into four areas:⁵ quality, coverage, management efficiency, and managerial finance efficiency. The indicators are expressed as a percentage, and averaged (with equal weight). Finally, the firms are ranked according to the score obtained within four groups, determined by the number of connections (small, with less than 10,000 connections; medium, with between 10,000 and 40,000 connections; and big, with more than 40,000 connections). See the results of the benchmarking for 2013 in Table 3, in the Appendix.

Berg & Lin (2008) evaluate the consistency of SUNASS's benchmarking method, in comparison to other frequently-used methodologies, such as regression, DEA (deterministic and stochastic), and stochastic frontier. The advantage of the alternative methodologies is that, generally, they consider the role of each indicator as either input, output, or "contextual" variable - that is, variables that characterize the operating environment of the firm, i.e., (1) they are outside the control of the firm; and (2) affect either input usage, or output production.⁶

Given the above discussion, unsurprisingly, the study found that the DEA and SFA-based methods generally produce consistent rankings, differently to those of the SUNASS and regression methods. In particular, the authors trace the major differences between methodologies that acknowledge input-output causality relations and SUNASS's simple benchmarking methodology in units that, although show low output levels, also show

⁵The number of indicators has risen in recent years, so that, for example, thirteen indicators were used in the 2013 benchmarking exercise.

⁶Besides the previously referenced studies, see also Thanassoulis (2000), for a review of the use of DEA techniques in the regulation of water companies in the UK.

low input usage. These units would obtain low scores by definition under the simple average of SUNASS's indicators. The optimization-based techniques, on the other hand, would recognize that some of this output performance might be explained by the low availability of inputs.

I extend the deterministic DEA methodology used in the previous study, by incorporating the influence of the firms' context of operation. In particular, I consider the influence of the population density, given the extensively documented economies of density present in the sector - see De Witte & Saal (2010), Vidoli (2011).

Methodology

Consider a vector of inputs, $X \in \mathbb{R}^p$, used to produce a vector of outputs, $Y \in \mathbb{R}^q$. Then, the production set is defined as: $\Psi = \{(x, y) | x \text{ can produce } y\}$. In this context, the Farrell's radial input efficiency measure for a DMU using input vector x to produce output y can be defined as:

$$\theta(x, y) \equiv \inf\{\theta | (\theta x, y) \in \Psi\} \quad (1)$$

This is an input-oriented efficiency measure: it calculates the maximum proportional (i.e., radial) decrease in input usage, θ , that is technically feasible while keeping the production vector y constant.

DEA is an empirical way to assess the Farrell input efficiency of a firm, relative to the observed performance of a group of comparable firms, or peers. That is, DEA takes all the units' input and output combinations and use them to form an empirical set of production possibilities, $\hat{\Psi}$. This set reveals what combinations of inputs and outputs are possible, *given the observed input-output combinations of the real units* (plus additional assumptions specified below). Given that it assess the unit's efficiency based on the observed performance the firm's peers, DEA can be seen as a benchmarking tool.

To be more concrete, consider the following typical assumptions for the empirical production possibilities set, $\hat{\Psi}$, under the DEA approach:

- Convexity: given two observed input-output configurations, any linear combination of them also belongs to $\hat{\Psi}$.
- Free disposal: given an input-output configuration in $\hat{\Psi}$, any other configuration with either lower output or higher input also belongs to $\hat{\Psi}$.
- Constant (CRS) or variable (VRS) returns to scale: under CRS any input-output configuration in $\hat{\Psi}$ is scalable, that is, it can be implemented any number of times. Under VRS, this is not the case.

Now consider a group of decision-making units (DMUs), $j = 1, \dots, J$. Under the previous assumptions, the CRS and VRS empirical production possibilities can be determined in reference to the observed performance of all the units in the group, as follows:

$$\hat{\Psi}^{CRS} = \{(x, y) \in \mathbb{R}_+^{M+P} | x \leq \sum_{j \in J} \lambda_j x_j, y \geq \sum_{j \in J} \lambda_j y_j, \lambda_j \geq 0, \forall j \in J\} \quad (2)$$

$$\hat{\Psi}^{VRS} = \{(x, y) \in \mathbb{R}_+^{M+P} | x \leq \sum_{j \in J} \lambda_j x_j, y \geq \sum_{j \in J} \lambda_j y_j, \sum_{j \in J} \lambda_j = 1, \lambda_j \geq 0, \forall j \in J\} \quad (3)$$

Then, the DEA input usage efficiency can be calculated by applying Farrell's efficiency definition to any of these production possibilities sets (under the CRS or VRS assumption, respectively). For example, under the VRS assumption, a firm i with observed input-output configuration (x_i, y_i) has an input usage efficiency of:

$$\theta_i^{VRS} \equiv \theta^{VRS}(x_i, y_i) = \inf\{\theta | (\theta x_i, y_i) \in \hat{\Psi}^{VRS}\} \quad (4)$$

For example, if $\theta_i^{VRS} = 0.7$, it would mean that DMU i could reduce its inputs usage by up to 30% (in every input dimension), and still be able to produce the same output vector y_i . A fully input efficient unit would have $\theta^{VRS} = 1$ (no proportional input reduction is possible). This would mean that there is no other unit in the sample (or linear combination of them) that produces the same level of output, with a lower amount of inputs. As can be seen, this is a *relative* measure of efficiency because it defines efficient performance based on the observed performance of other units, not up to an ideal or absolute standard of efficiency.

Notice that the previous definition considers all the units as comparable. However, what if the contexts in which the units operate are *too* different? In the case of water distribution, it could be very different to provide the service in cities with different population densities. Arguably, it could be much less input-demanding to increase the coverage of the service in cities with higher population density. More generally, consider a *contextual* variable Z , that captures this diversity. One would want to compare cities with relatively similar values of this variable. Consider a firm i , with input-output configuration (x_i, y_i) and contextual variable z_i . We can define a production possibilities set, conditional on the value of its contextual variable z_i (I only present the CRS case for brevity):

$$\hat{\Psi}^{CRS}(z_i) = \{(x, y) | x \leq \sum_{j \in J} \lambda_j x_j, y \geq \sum_{j \in J} \lambda_j y_j, \lambda_j \geq 0, \forall j \in J \text{ such that } z_i - h \leq z_j \leq z_i + h\} \quad (5)$$

In this definition, the comparison set for unit i is formed following a similar procedure as before, but now considering only the units (indexed as j) that have a value z_j within a distance h of z_i . That is, the comparison group here considers units with a relatively similar value of z (the similarity is controlled by appropriately choosing the bandwidth parameter, h). Following Daraio & Simar (2005), we denote this as a *conditional* DEA efficiency index.

Model Specification and Data

The performance of 43 firms from 2006 to 2013 were studied, which is the full set of firms operating in the sector with the exception of the firm operating in the capital city, SEDAPAL, and a few small companies (due to missing data). This firm is excluded because its operating environment is radically different from the rest of the country: it serves almost 1.4 million active connections, compared to an average of 38 thousand for the firms in other cities. Given that having such a different observation in the sample may distort the performance comparisons, it is therefore excluded.

In order to deal with the panel data structure, the information for all the years was combined, and a single efficient frontier was calculated. In this way, the observed performance of every unit is compared to a single benchmark, which is intended to be formed by the best observed performances along all the years in the sample. Following this practice, Estache, Rossi & Ruzzier (2004) study of electric utilities in South America was followed, as well as previous studies about the Peruvian water sector specifically, such as Berg & Lin (2008).

The last study was also followed, as well as the applied literature in the sector and in this industry in particular (Corton, 2003; Lin, 2005), to specify the inputs and outputs of the production model. The list of inputs includes the operating costs, the number of employees and the total length of the distribution network. The operating costs are used as a proxy for the use of intermediate inputs in the production and delivery process, while the number of employees measure the amount of labor (given the absence of more precise measures of labor input usage), and the length of the distribution network proxies the amount of the capital input utilized (given the usual problems in measuring capital).

Regarding the outputs, the list includes the total amount of water billed, the coverage ratio, and the degree of continuity of the service. This intends to capture not only output, but also quality dimensions (Lin, 2005; Picazo-Tadeo, Saez-Fernandez & Gonzalez-Gomez, 2008). For example, the amount of water billed indirectly measures a (negative) dimension of quality, such as the amount of water losses in the network. This problem is regarded as highly relevant in the Peruvian case (Berg & Lin, 2008) - e.g., by 2013 only around 65% of the water produced was actually billed, in average for all operators.

Table 1

Summary Statistics

	Mean	St. Dev.	Min	Max
Outputs				
Water Billed (m3)	7'766,287	9'067,781	348,231	44'531,840
Coverage (%)	83	12	29	100
Continuity (hs/day)	15	6	0	24
Inputs				
Operating costs (S/.)	11'275,086	16'503,797	260,677	92'253,000
Workers	132	144	2	740
Total water network length (kms)	336	388	28	2,044
Context				
Population density (habs/km)	627	255	82	1,662

The other two variables included as outputs, the coverage and continuity of the service provision, can be seen as fully quality indicators. As shown in Lin (2005) (a benchmarking study, in the stochastic frontier analysis framework), these variables seem to have a significant incidence on the firms' operating cost efficiencies in this sector. Therefore, it is fruitful to include them also as determinants of productive efficiency. The coverage is calculated as the ratio between the estimated population served by the operator, and the total amount of population within the area of service. Continuity is measured as the average number of hours that the service is operating on a daily basis.

Table 1 shows the summary statistics of the aforementioned variables. Notice that there is still a considerable degree of heterogeneity left in the sample, in spite of having excluded the operator in Lima and those with a high degree of missing information (mostly very small networks). In particular, the population density (our proposed determinant of the operating context) has a big range of variation, from 82 to 1,662 inhabitants by kilometer of water network. Figure 1 shows an histogram for this variable, which illustrates the high heterogeneity present in the sample. This suggests that the differing contexts could be relevant to explain part of the observed operating performance.

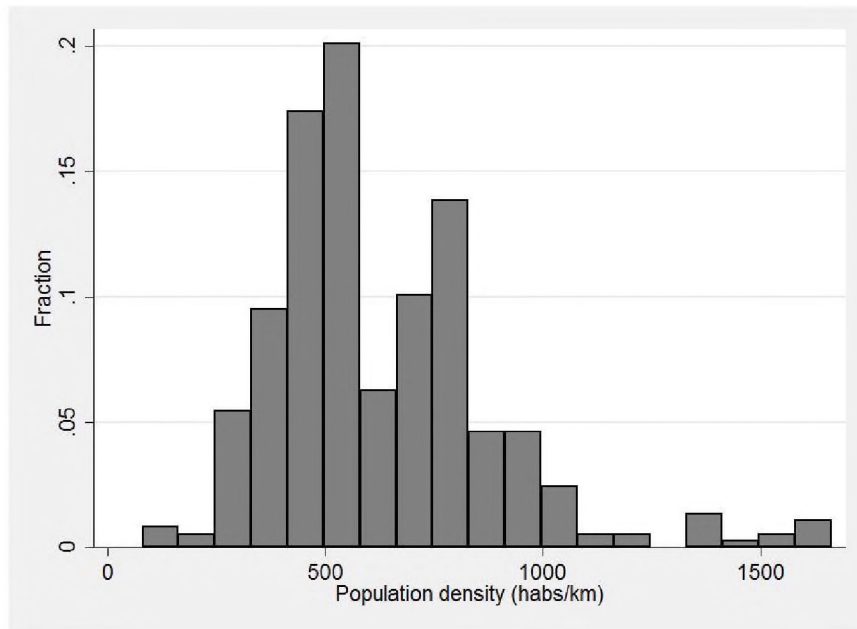

Figure 1. Histogram of population density

Results

The Table 2, and Figures 2 and 3, show the statistics and histograms, respectively, of the DEA efficiency scores calculated under the VRS and CRS assumptions - the detailed results for every firm in every year are shown in Tables 4 and 6 in the Appendix. It is important to remember at this point that the efficiency assessments are *relative*: a fully efficient firm under this approach (i.e., with an efficiency score of 1) does not necessarily mean that the firm is technically fully efficient, but only than its performance is the best of the pool of firms under evaluation.

The distribution of the unconditional efficiency scores in both, the VRS and CRS cases, show an ample variability (particularly in the CRS case, as expected). Taken at face value, the VRS results imply that at the average observed performance (0.788), input usage could have been decreased by 21.2% in every dimension without affecting the output and quality produced, only taking as a reference the observed performance in the sample chosen. In the CRS case, given the more ample distribution, the average performance is of only 0.588.

Table 2

Efficiency Scores Statistics

	Mean	St. Dev.	Min	p25	p50	p75	Max
Unconditional							
CRS	0.588	0.221	0.234	0.416	0.507	0.767	1.000
VRS	0.788	0.206	0.262	0.658	0.830	1.000	1.000
Conditional							
CRS	0.797	0.193	0.387	0.639	0.830	1.000	1.000
VRS	0.901	0.145	0.441	0.837	0.994	1.000	1.000

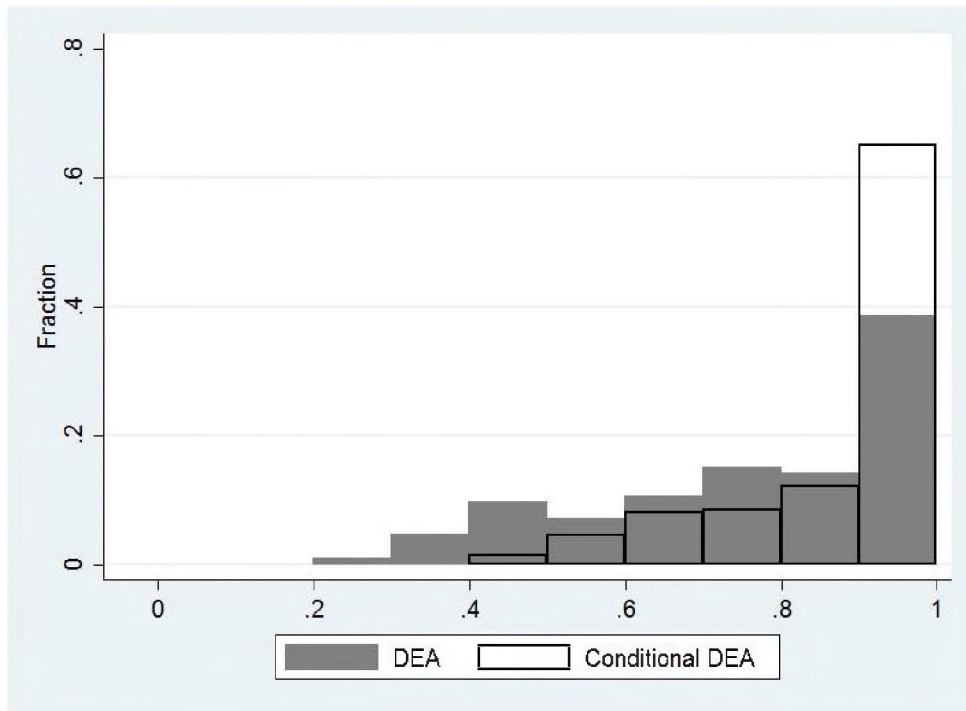

Figure 2. Histogram of DEA efficiency scores (VRS)

Figure 3. Histogram of DEA efficiency scores (CRS)

Figure 4. Ratio of unconditional over conditional DEA versus population density (CRS)

The distribution of the conditional DEA estimates are, naturally, less disperse - this is expected because with conditional DEA each performance is compared only to a subset of the sample, those observations with similar levels of population density. In both the CRS and VRS cases, the average efficiency increases substantially. In the CRS case it reaches 0.797 (up from 0.588 in the unconditional DEA), while in the VRS case is now 0.901 (up from 0.788). That is, the distance between the observed best and worst performances could be explained in a significant degree by different contexts in which the firms perform. The detailed calculated scores are presented in Tables 5 and 7 in the Appendix.

To get a sense of how much the context of operation could be affecting the production possibilities of the firms, I compare the ratio of the unconditional over the conditional DEA scores with the population density. Figures 4 and 5 plots these observations (denominated as R in the figures), along with a non-parametric (lowess) regression estimate. The ratio of the DEA efficiency scores measures the distance between the unconditional and conditional production possibilities ($\hat{\Psi}$ and $\hat{\Psi}(z)$ in the methodological section). When the ratio is closer to one it means that the both estimates are exactly equal, so conditioning on the context would not affect the production possibilities of the firms. The farther the measure deviates from one, on the contrary, would mean that there is a significant effect. We can see that in both the CRS and VRS cases there seems to be positive relation between the ratios and population density, stronger in the CRS case. We can interpret this as saying that low population densities seem to affect the production possibilities of the firms.

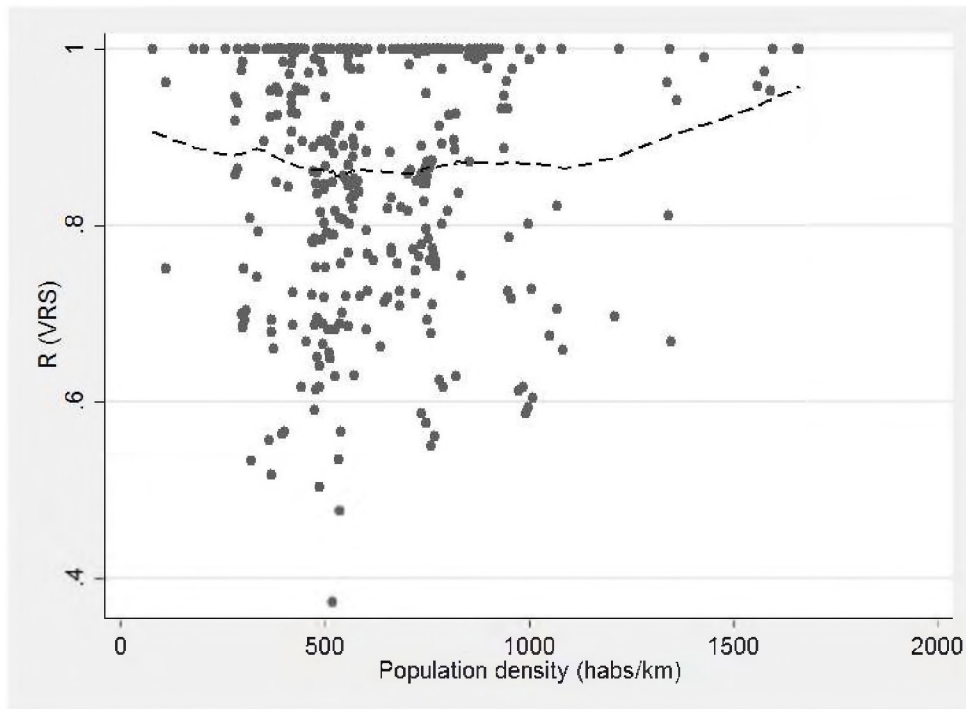

Figure 5. Ratio of unconditional over conditional DEA versus population density (VRS)

Conclusions

In this study, production performance benchmarking techniques were applied, within the DEA framework, to compare the input usage efficiency of the water companies in Peru. The advantage of the DEA approach is that it does not only compares output and quality performance across companies, but also takes into consideration the input usage level. As noticed by Berg & Lin (2008), simple performance measures, like those used by SUNASS, mostly omit the input side of the production process.

On the other hand, in the DEA approach it could be complicated to account for the different contexts in which the companies operate, in comparison to regression methods, for example. At the same time, there is also the concern that the perceived differential performance could actually be explained in some degree by these differing contexts (Tupper & Resende, 2004). In this study I apply an extension of the usual input-oriented DEA benchmarking methodology to account for the possibly differential contexts. The conditional DEA method (Daraio & Simar, 2005) relies on comparing units with approximately similar contexts of operation, where this is quantified by a so-called “contextual variable”.

Conditional DEA scores were calculated by conditioning on the population density in the area of operation of each company. I find that controlling for the context of operation in this way affects in an economically significant amount the calculated efficiencies, and therefore can affect the performance benchmarking of water companies in Peru.
